Abstract

Over-activation of the fibrinolytic system may result in proteolytic destruction of fibrinogen. However, the effect of the degradation products formed during fibrinogenolysis on fibrinolytic process and plasminogen/plasmin properties remains unclear. To investigate this effect and its mechanism, the ability of fibrinogen fragments E and D to act on plasminogen and tPA binding, proenzyme activation, fibrin clot lysis and plasmin inhibition by plasma α2-antiplasmin, were studied. It was found that early product fragment E binds to plasminogen and tissue-type plasminogen activator and enhances plasminogen conversion into plasmin. C-terminal lysine residues of all 3 chains pair and 16 or 23 amino acid residues of Aa-chain are essential for this process. C-terminal lysines of fragment E Aa- and γ-chains and lysine-binding site of tPA kringle 2 are responsible for the interaction between these proteins. Binding of fragment E to plasminogen is provided by N-terminal Aα1–19 and C-terminal Bβ120–122 regions. Late plasmic fibrinogen degradation product fragment E loses the ability to potentiate plasmin generation but can bind proenzyme and its activator. Fragment D has no binding properties towards plasminogen and tPA. None of fibrinogen fragments protects plasmin from α2-antiplasmin inhibition. It is concluded that at over-activation of the fibrinolytic system and subsequent fibrinogenolysis, the products of fibrinogen degradation, can bind plasminogen and tPA and potentiate generation of plasmin, which will be neutralized under the normal level of the plasmin inhibitor.

Key words

fibrinolysis, plasminogen, tissue-type plasminogen activator, fibrinogen degradation products

INTRODUCTION

Fibrinolytic system activation is an appropriate response to blood clotting and mainly serves for the lysis of polymeric fibrin deposition. The main fibrinolytic enzyme plasmin is generated from inert precursor plasminogen by either tissue-type plasminogen activator (tPA) or urokinase-type plasminogen activator (uPA). Plasminogen and tPA from plasma bind to specific sites in fibrin during fibrinogen conversion to fibrin, and plasminogen activator cleaves proenzyme into plasmin [1]. Plasmin then destructs fibrin into soluble fibrin degradation products (noncovalent DDE complex, cross-linked dimeric fragment D-D and fragment E) that release into the bloodstream. The remaining enzyme, after clot dissolution, is inactivated by plasma inhibitors (mainly by α2-antiplasmin) [2].

Under pathophysiological conditions, over-activation of the fibrinolytic system can cause proteolytic destruction of fibrinogen, and severe bleeding may occur. Fibrinogenolysis may complicate various disorders, such as disseminated intravascular coagulopathy, severe liver disease, tumour, vascular surgery, inflammation, and an inherited or acquired defective fibrinolytic mechanism [3, 4]. Common adverse effects of all the thrombolytic drugs are the bleeding complications related to systemic fibrinogenolysis and lysis of normal hemostatic plugs. Fibrinogen destruction results in fragments D and E formation that is consequence of plasmin generation within the general blood circulation and exceeded neutralizing ability of plasma inhibitors of fibrinolysis [4].

Fibrinogen/fibrin degradation products (FDPs) are the markers for the fibrinolysis activation level, FDPs concentration in blood becomes increased under the thrombotic disorder, surgery complications, etc. FDPs participate in a range biological process, such as platelet activation, adhesion and aggregation, vessel wall permeability, fibrinogen synthesis, and blood cell function. Fibrin fragments are characterized by the binding affinity to the t-PA and plasminogen, effect on fibrin polymerization and activation process [5, 6]. Fragment D and D-dimer inhibit fibrin polymerization. However, the effect of degradation products formed during fibrinogenolysis on the fibrinolytic process and plasminogen/fibrin properties, remains unclear. The presented study addresses these issues.

To investigate this effect and its mechanism, the ability of fibrinogen fragments E and D to act on various stages of the fibrinolytic process, namely, on plasminogen and tPA binding, proenzyme activation, fibrin clot lysis and plasmin inhibition by plasma α2-antiplasmin, was studied. To determine the structures of the fragment E molecule responsible for the interactions with fibrinolytic system components, early and late fibrinogen degradation products and fragments E treated by carboxypeptidase B and thrombin were used.

MATERIALS AND METHODS

Fibrinogen was purified from human plasma by fractionation with sodium sulfate [7]. Glu-plasminogen was prepared from citrate donor plasma using the Lysine-sepharose affinity
chromatography [8]. Plasmin was obtained by activation of Glu-plasminogen with urokinase, immobilized to Sepharose 4B [8]. The recombinant single-chain tPA was a Boehringer Ingelheim product known under the trade name “Actylise”.

Fibrinogen degradation products were prepared from plasmin digest of human fibrinogen. Digestion was performed at 37°C in 0.05 M TBS with 0.15 M NaCl (pH 7.4), concentration of fibrinogen was 10 mg/ml, plasmin – 0.2 CU/ml, calcium ion – 5 mM. Early and late plasmic degradation products were obtained after 1 and 6 hours of hydrolysis, respectively. Reaction was inhibited by 1,000 KIU aprotinin (Merckle GmbH) per 1 ml of reactive solution. Early (E) and late (E) fragments E and fragment D were purified by ion-exchange chromatography on CM-Sephadex G-50, as described elsewhere [9].

Early fragment E without C-terminal lysines (E_CFP) was prepared by carboxypeptidase B (Sigma) treatment (final molar ratio to fragment – 1/50) for 30 min at room temperature in 0.1 M TBS (pH 8.1).

Early fragment E without fibrinopeptide A (E_FPA) was prepared by thrombin (Sigma) treatment (3.3 NIH units of thrombin per 1 mg fragment) for 30 min. Thrombin was removed by Heparin-Sepharose 6B.

Monomeric desAB-fibrin was obtained by dissolving a thrombin fibrin clot formed in the presence of 50 mM ε-aminocaproic acid (ε-ACA) and parahydroxy mercury benzoate (0.35 mg/ml) in 20 mM acetic acid, as described elsewhere [10].

All proteins were tested for homogeneity by 8–12% SDS-PAGE. Protein concentrations were calculated by measurement of the absorbance at 280 and 320 nm using E_280 and molecular weights respectively: Glu-plasminogen, 17.0 and 92 000; plasmin, 17.0 and 84 000; tPA, 20.0 and 59 000; fibrinogen, 15.5 and 340 000; fragment D, 20.0 and 95 000; fragment E, 10.0 and 60 000; fragment E, 10.0 and 45 000.

The stimulating effect of fibrinogen fragments on the tPA-catalyzed conversion of plasminogen into plasmin was evaluated by determination of the amidolytic activity of the newly-formed plasmin with chromogenic substrate S-2251 (H-D-valyl-L-leucyl-L-lysine-p-nitroanilide). The assay system contained 0.22 µM Glu-plasminogen, 0.09 nM tPA, 0.3 mM S-2251, and 0.625 µM monomeric desAB-fibrin and/or 0.22 µM fibrinogen fragments in 0.05 M TBS with 0.15 M NaCl (pH 7.4) containing 0.05% Tween 80. The assay was performed in a microtiter 96-well plate at 37°C. The amidolytic activity was determined by measurement of the absorbance at 405 nm using Titertek Multiscan MC 96-well plate reader (Berthold Detection Systems).

Isomolar series were carried out using chromogenic substrate assay, as described above. The total number of Glu-plasminogen and fragment E molecules in each series was the same. Molar ratio plasminogen/fragment was from 9/1 – 1/9. Maximum concentration of each protein was 0.39 µM.

Binding assay was performed using the avidin-biotin system (Thermo Scientific). Biotin labeling of Glu-plasminogen and tPA was carried out according to the manufacturer’s recommendation. The wells of high binding polystyrene microtitrate plates (Nunc MaxiSorp) were coated with 1µg fragments in 0.1 ml 0.01 M sodium phosphate buffer (pH 7.4) and 0.15 M NaCl at 4°C overnight. After binding, the excess fragments were removed by washing buffer with 0.1% Tween 80. To avoid nonspecific sorption, 2% BSA was pipetted into the plate wells, incubated for 2 hours at 37°C and washed out. After washing procedures, binding fragments in each well were incubated with 0.1 ml biotinylated plasminogen or tPA for 4 hours at 37°C and washed out. Then, 0.1 ml avidin-phosphatase (solved as manufacturer’s recommendation) was added into the wells and washed out after 60 min incubation. 0.1 ml alkaline phosphatase substrate (1 mg/ml p-nitrophenyl phosphate in 10% diethanolamine, pH 9.8) was pipetted into the wells and incubated for 2 hour at 37°C. Binding of biotin labeled proteins with fragments immobilized on well surface was estimated by measurement of p-nitrophenol absorbance at 405 nm, using a Titertek Multiscan reader.

For the estimation of fibrinolytic activity of plasmin, the turbidimetric method was applied, as described in [11]. The final concentration of desAB-fibrin was 0.6 µM, plasmin – 0.02 µM. The rate of fibrin clot lysis by plasmin was calculated as V=1/t_1/2. Time of 50% lysis (t_1/2) was measured as the time period from the initiation step of the clot formation until the step characterized by 50% fall in absorbance from maximum.

The blood plasma α2-antiplasmin effect was evaluated by inhibition of plasmin fibrinolytic activity. The blood plasma containing 0.06 mg/ml of inhibitor was added into the reaction mixture. Final molar ratio of α2-antiplasmin (MW 62 000) to enzyme was 1/1 (0.02 µM). The rate of fibrin lysis by plasmin without plasma addition was taken as 100%.

RESULTS

To investigate the ability of fibrinogen degradation products to affect the fibrinolytic system function, the effect of fragments E and D on Glu-plasminogen activation by rtPA on desAB-fibrin was assessed (Fig. 1). Each fragment was added into reaction medium in equimolar amounts to Glu-plasminogen. It was found that neither fragment E nor fragment D changed potentiation of plasmin generation by polymeric desAB-fibrin. However, it has been demonstrated that fragment E, but not fragments E, D and potentiate plasminogen activation by tPA (Fig. 2). The rate of E effect was approximately 30% of desAB-fibrin potentiation.

![Figure 1](attachment:image.png)

**Figure 1.** tPA-catalysed Glu-plasminogen activation on desAB-fibrin in fibrinogen fragments presence. Activation was measured by amidolytic activity assay. Absorbance of newly-formed p-nitroanilin from S_2251 indicates the rate of the plasmin formation from its precursor. Presence of fragments D and E (equimolar to plasminogen) does not change the kinetics of activation process.
By applying the method of izomolar-series, the maximum potentiating effect of fragment $E_4$ on tPA-catalysed plasminogen activation was established (Fig. 3). The effect was observed at a molar ratio of plasminogen to fragment $E_4$ 4/1.

To determine the significance of some parts of the fragment E molecule for interaction with fibrinolytic system components, the tPA and Glu-plasminogen binding to fragments $E_{EL}$, $E_{CPB}$ was investigated by using the avidin-biotin system (Fig. 4). It was shown that tPA affinity to $E_4$ and $E_6$ was the same, whereas carboxy-terminal lysines elimination resulted in a 9-fold decrease of the activator binding. Furthermore, tPA binding to fragment E decreased in the presence of ε-ACA, which in 0.1 M concentration almost suppressed interaction between fragment and lysine-binding sites of the activator (Fig. 5).

The results obtained on Glu-plasminogen binding to fragments $E_4$, $E_6$, and $E_{CPB}$ are shown in Fig. 6. Glu-plasminogen was bound to early degradation product $E_6$ in higher quantities and with a higher affinity then to late
that the fragment D molecule does not comprise the exposed residues from Aα-chain of Eγ, thrombin resulted in a 25% reduction of the plasminogen activation rate (Fig. 7). On the other hand, treatment of Eγ by carboxypeptidase D almost abolished proenzyme activation by tPA.

Chromogenic substrate assay of plasmin generation demonstrated that removing 16 amino-terminal amino-acid residues from Aα-chain of Eγ by thrombin resulted in a 25% reduction of the plasminogen activation rate (Fig. 7). On the other hand, treatment of Eγ by carboxypeptidase D almost abolished proenzyme activation by tPA.

The fibrinogen molecule contains specific plasminogen binding sites which are hidden in the native state but exposed under fibrin polymerisation. During the fibrinogenolysis, plasmin cleaves fibroin into fragments E and D. Fragment D is known to have a plasminogen-binding activity of fibrinogen fragments. The same pattern of tPA binding to fibrinogen fragments indicates that the 24 N-terminal amino acids of the Aα-chain is unnecessary for the interaction with tPA.

DISCUSSION

The fibrinogen molecule contains specific plasminogen- and tPA-binding sites which are hidden in the native state but exposed under fibrin polymerisation. During the fibrinogenolysis, plasmin cleaves fibrinogen into fragments E and D. Fragment D is known to have a plasminogen-binding site in the Aα148–160 region, and the tPA-binding site in the γ312–324 region [12]. However, the effect of fragment D on plasminogen activation by tPA, with and without fibrin, was not observed (Fig. 1, 2). The absence of the effect suggests that the fragment D molecule does not comprise the exposed sites for plasminogen activation. This data is consistent with the concept of fibrinolysis initiation: that exposition of plasminogen- and tPA-binding sites in D-domain with subsequent plasin generation require conformational changes occurring upon polymerization [1].

It was shown that fragment E can bind Glu- and Lys-plasminogen with the same affinity in 2 binding regions. Isolated plasminogen fragments K1–3 and mini-plasminogen also specifically bind to this fragment [13, 14]. The presented data demonstrates that early plasmic degradation product fragment Eγ can stimulate plasmin generation by tissue-type activator, while late fragment Eδ does not potentiate this process (Fig. 2). Maximum potentiation effect at molar ratio plasminogen to Eγ 4/1 suggests that 4 molecules is the maximum amount of plasminogen bound to Eγ (Fig. 3).

Fragment Eγ, unable to stimulate plasminogen activation, differs from Eγ in the lack of 24 N-terminal amino acids in the Aα-chain and C-terminal Bβ121(122) amino acids (Fig. 8). It is probable that the presence of these amino acids in Eγ causes its potentiation effect, and is essential for plasminogen and tPA binding.

tPA binds to partially digested fibrin and FDPs via their C-terminal lysines by lysine-binding site of kringle 2 [17]. Probably, a similar mechanism is presented in the binding to fibrinogen fragments. The same pattern of tPA binding to Eγ and Eδ fragments indicates that the 24 N-terminal amino acids of the Aα-chain is unnecessary for the interaction with activator. This is supported by the data about tPA-binding ability of fibrin fragments Eγ and Eγ, which is similar to Eγ and Eγ, respectively [18]. On the other hand, the presence of C-terminal lysines is urgent for tPA binding to fragment Eγ. This is confirmed by the reduction of the activator binding in ε-ACA presence (Fig. 5).

Fragment E interaction with Glu-plasminogen depends on C-terminal lysines and N-terminal Aα1–17 (Fig. 6, 7). Its C-terminal lysines are important but not crucial for this process. Carboxypeptidase D treatment only partially declined its level, although without lysine residues Aα78, Bβ121–122 and γ58 Eγ completely lose their potentiating effect on plasminogen activation by tPA.

C-terminal lysines of all 3 chains pair and 16 or 23 N-terminal residues of Aα-chain are necessary for fragment E...
stimulating action on plasmin generation. Structure analysis of $E_A$, $E_B$, $E_D$, and obtained data allow assuming the interaction between C-terminal lysine of $\alpha\alpha$- and $\gamma$-chains and lysine-binding site of tPA kringle 2. The presence of thrombin-activable fibrinolysis inhibitor in circulation can attenuate fragment E-mediated plasminogen activation by removing of C-terminal lysines, and in this way reduce the stability of E for tissue-type plasminogen activator [18].

The lack of $\alpha\alpha$1–6 and $\beta\beta$120–122 demolishes the 2-sites binding of the plasminogen molecule. Thus, complete plasmic digestion of fibrinogen fragment E results in the total reduction of the potentiating ability. Therefore, the remaining plasminogen and tPA binding ability of E, can decrease fibrinolytic activation rate by the complex formation with proenzyme and its activator without enzyme generation.

Fibrinogen fragments D and E, compared to fibrin, have lower affinity to plasmin and do not attenuate the clot lysis. Excessive amounts of plasmin which get into bloodstream are fast inhibited by $\alpha\alpha$2-antiplasmin [19]. Plasmin bound to fibrinogen fragments is susceptible to inhibition by $\alpha\alpha$2-antiplasmin. Under the normal level of the plasmin inhibitor, the fragments-associated enzyme is neutralized. In other cases, this may result in non-specific proteolysis and further bleeding.

CONCLUSIONS

The results of the presented study demonstrate that fibrinogen degradation products can affect the fibrinolytic process in several ways. Early product fragment $E_A$ binds to plasminogen and tissue-type plasminogen activator, and enhances plasminogen conversion into plasmin. For this process, all C-terminal lysine residues of 3 chains pair and 16 or 23 N-terminal amino acid residues of $\alpha\alpha$-chain are essential. C-terminal lysines of fragment $E_{\alpha\alpha}$- and $\gamma$-chains and lysine-binding site of tPA kringle 2 are responsible for the interaction between these proteins. Binding of fragment E to plasminogen is provided by the N-terminal $\alpha\alpha$1–19 and C-terminal $\beta\beta$120–122 regions. Late plasmic fibrinogen digestion product fragment $E_D$ loses the ability to potentiate plasmin generation, but can bind proenzyme and its activator. Fragment D has no binding abilities towards plasminogen and tPA. None of fibrinogen fragments protected plasmin from $\alpha\alpha$2-antiplasmin inhibition. It is concluded that at over-activation of the fibrinolytic system and subsequent fibrinogenolysis, the products of fibrinogen degradation can bind plasminogen and tPA and potentiate the generation of plasmin, which will be inhibited under the normal level of the plasmin inhibitor.
